Abstract. The propagation of a modulated beam of charged particles in a planar crystal channel is investigated. It is demonstrated that the beam preserves its modulation at sufficiently large penetration depths which opens the prospect of using a crystalline undulator as a coherent source of hard X rays. This finding is a crucial milestone in developing a new type of lasers radiating in the hard X ray and gamma ray range.

PACS numbers: 61.85.+p, 05.20.Dd, 41.60.-m

In this Letter we study for the first time the evolution of a modulated particle beam in a bent planar crystal channel and demonstrate that it preserves its modulation at sufficiently large penetration depths which opens the prospect of using a crystalline undulator as a coherent source of hard X rays. Solving this problem is of crucial importance in the theory of the Crystal Undulator based Laser (CUL) [1, 2, 3] — a new electromagnetic radiation source in hard X and gamma ray range.

Channeling takes place if charged particles enter a single crystal at small angle with respect to crystallographic planes or axes [4]. The particles get confined by the interplanar or axial potential and follow the shape of the corresponding planes and axes.

A single crystal with periodically bent crystallographic planes can force channeling particles to move along nearly sinusoidal trajectories and radiate in hard X and gamma ray frequency range (see Fig. 1). The feasibility of such a device, known as the 'crystalline undulator', was demonstrated theoretically a decade ago [1] (further developments as well as historical references are reviewed in [5]). More recently, an electron based crystalline undulator has been proposed [6].

Figure 1. Schematic representation of the crystalline undulator.

The advantage of the crystalline undulator is in extremely strong electrostatic fields inside a crystal which are able to steer the particles much more effectively than even the most advanced superconductive magnets. This fact allows to make the period λ_u of the crystalline undulator in the range of hundreds or tens micron which is two to three orders of magnitude smaller than that of conventional undulator. Therefore the wavelength of the produced radiation $\lambda \sim \lambda_u/(2\gamma^2)$ ($\gamma \sim 10^3$ – 10^4 being the Lorentz factor of the particle) can reach the (sub)picometer range, where conventional sources with comparable intensity are unavailable [7].

Even more powerful and coherent radiation will be emitted if the probability density of the particles in the beam is modulated in the longitudinal direction with the period

λ , equal to the wavelength of the emitted radiation. In this case, the electromagnetic waves emitted in the forward direction by different particles have approximately the same phase [8]. Therefore, the intensity of the radiation becomes proportional to the beam density squared (in contrast to the linear proportionality for an unmodulated beam). This increases the photon flux *by orders of magnitude* relative to the radiation of unmodulated beam of the same density. The radiation of a modulated beam in an undulator is a keystone of the physics of free-electron lasers [9]. It can be considered as a classical counterpart of the stimulated emission in quantum physics. Therefore, if similar phenomenon takes place in a crystalline undulator, it can be referred to as the *lasing regime of the crystalline undulator*.

The feasibility of CUL radiating in hard X ray and gamma ray range was considered for the first time in [1, 2]. Recently, a two-crystal scheme, the gamma klystron, has been proposed [3].

A simplified model used in the cited papers assumed that all particle trajectories follow exactly the shape of the bent channel. In reality, however, the particle moving along the channel also oscillates in the transverse direction with respect to the channel axis (see the shape of the trajectory in Fig. 1). Different particles have different amplitudes of the oscillations inside the channel (Fig. 2, upper panel). Similarly, the

Figure 2. Due to different amplitudes of channeling oscillation (upper panel) and different momentum directions in the (xz) plane (lower panel), the initially modulated beam gets demodulated. Open and filled circles denotes the same particles at the crystal entrance and after travelling some distance in the crystal channel, respectively.

directions of particle momenta in (xz) plane are slightly different (Fig. 2, lower panel). Even if the speed of the particles along their trajectories is the same, the particles oscillating with different amplitudes or the particles with different trajectory slopes with respect to z axis have slightly different components of their velocities along the channel. As a result, the beam gets demodulated. An additional contribution to the beam demodulation comes from incoherent collisions of the channeling particles with the crystal constituents.

In the case of an unmodulated beam, the length of the crystalline undulator and, consequently, the maximum accessible intensity of the radiation is limited by the dechanneling process. The channeling particle gradually gains the energy of transverse oscillation due to collisions with crystal constituents. At some point this energy exceeds the maximum value of the interplanar potential and the particle leaves the channel. The average penetration length at which this happens is known as the *dechanneling length*. The dechanneled particle does not follow the sinusoidal shape of the channel any more and, therefore, does not contribute to the undulator radiation. Hence, the reasonable length of the crystalline undulator is limited to a few dechanneling lengths. A longer crystal would attenuate rather than produce the radiation. Since the intensity of the undulator radiation is proportional to the undulator length squared, the dechanneling length and the attenuation length are the main restricting factors that have to be taken into account when the radiation output is calculated.

In contrast, not only the shape of the trajectory but also the particles positions with respect to each other along z axis are important for the lasing regime. If these positions become random because of the beam demodulation, the intensity of the radiation drops even if the particles are still in the channeling mode. Hence, it is the beam demodulation rather than dechanneling that restricts the intensity of the radiation of CUL. Understanding this process and estimating the characteristic length at which this phenomenon takes place is, therefore, a cornerstone of the theory of this new radiation source.

Let us consider the distribution $f(t, s; \xi, E_y)$ of the beam particles with respect to the angle between the particle trajectory and axis z in the (xz) plane $\xi = \arcsin p_x/p \approx p_x/p$ and the energy of the channeling oscillation $E_y = p_y^2/2E + U(y)$ ‡. Here p , p_x and p_y are, respectively, the particle momentum and its x and y components, $U(y)$ is the interplanar potential which we approximate by a parabola $U(y) = U_{\max}(y/y_{\max})^2$, and E is the particle energy (we will consider only ultrarelativistic particles, therefore $E \approx p$). It can be shown that the evolution of this distribution in the crystal channel with the time t and the longitudinal coordinate (penetration depth into the crystal along the curved channel) s can be described by the following differential equation of Fokker-Planck type:

$$\frac{\partial f}{\partial t} + \frac{\partial f}{\partial s} v_s = D_0 \left[\frac{\partial}{\partial E_y} \left(E_y \frac{\partial f}{\partial E_y} \right) + \frac{1}{E} \frac{\partial^2 f}{\partial \xi^2} \right]. \quad (1)$$

‡ We chose the system of units in such a way that the speed of light is equal to unity. Therefore, mass, energy and momentum have the same dimensionality. This is also true for length and time.

Here D_0 is the diffusion coefficient that is dominated by the scattering of the beam particles by lattice electrons. The particle longitudinal velocity averaged over the undulator period, v_s , is given by

$$v_s = \left(1 - \frac{1}{2\gamma^2} - \frac{\xi^2}{2} - \frac{E_y}{2E}\right). \quad (2)$$

Equation (1) is akin to the equation describing dechanneling process (see e.g. [10]) and is derived in a similar way. The novel feature of it is the presence of time variable, which allows to describe time dependent (modulated) beams. Additionally, it takes into account scattering in the (x, z) plane.

If the beam is periodically modulated (bunched) the distribution can be represented as a Fourier series:

$$f(t, s; \xi, E_y) = \sum_{j=-\infty}^{\infty} g_j(s; \xi, E_y) \exp(ij\omega t). \quad (3)$$

with $g_j^*(s; \xi, E_y) = g_{-j}(s; \xi, E_y)$ to ensure the real value of the particle distribution. Since Eq. (1) is linear, it is sufficient to consider only one harmonic. Substituting $f(t, s; \xi, E_y) = g(s; \xi, E_y) \exp(i\omega t)$ one obtains

$$i\omega g(s; \xi, E_y) + \frac{\partial g}{\partial s} v_s = D_0 \left[\frac{\partial}{\partial E_y} \left(E_y \frac{\partial g}{\partial E_y} \right) + \frac{1}{E} \frac{\partial^2 g}{\partial \xi^2} \right]. \quad (4)$$

To simplify this equation, we make the substitution $g(s; \xi, E_y) = \exp(-i\omega s) \tilde{g}(s; \xi, E_y)$ and assume that the variation of $\tilde{g}(s; \xi, E_y)$ within the modulation period is small: $\partial \tilde{g} / \partial s \ll \omega \tilde{g}(s; \xi, E_y)$. This allows us to neglect the terms $(1-v_s) \partial \tilde{g} / \partial s$ while keeping the terms $(1-v_s) \omega \tilde{g}(s; \xi, E_y)$. The resultant partial differential equation for $\tilde{g}(s; \xi, E_y)$ can be solved by the method of separation of variables. Putting $\tilde{g}(s; \xi, E_y) = \mathcal{S}(s) \Xi(\xi) \mathcal{E}(E_y)$, we obtain a set of ordinary differential equations:

$$\frac{D_0}{E} \frac{1}{\Xi(\xi)} \frac{d^2 \Xi(\xi)}{d\xi^2} - i\omega \frac{\xi^2}{2} = \mathcal{C}_\xi, \quad (5)$$

$$\frac{D_0}{\mathcal{E}(E_y)} \frac{d}{dE_y} \left(E_y \frac{d\mathcal{E}(E_y)}{dE_y} \right) - i\omega \frac{E_y}{2E} = \mathcal{C}_y, \quad (6)$$

$$\frac{1}{\mathcal{S}(s)} \frac{d\mathcal{S}(s)}{ds} + \frac{i\omega}{2\gamma^2} = \mathcal{C}_s, \quad (7)$$

where $\mathcal{C}_s$, $\mathcal{C}_\xi$ and $\mathcal{C}_y$ do not depend on any of the variables s , ξ and E_y and satisfy the condition

$$\mathcal{C}_s = \mathcal{C}_\xi + \mathcal{C}_y. \quad (8)$$

Eq. (5) has the form of the Schrödinger equation for the harmonic oscillator. Its eigenvalues and eigenfunctions are, respectively,

$$\mathcal{C}_{\xi,n} = -(1+i) \sqrt{\frac{\omega D_0}{E}} \left(n + \frac{1}{2} \right), \quad n = 0, 1, 2, \dots \quad (9)$$

and

$$\Xi_n(\xi) = H_n \left(e^{i\pi/8} \sqrt{\frac{\omega E}{2D_0}} \xi \right) \exp \left(-\frac{1+i}{4} \sqrt{\frac{\omega E}{D_0}} \xi^2 \right). \quad (10)$$

Here $H_n(\dots)$ are Hermite polynomials.

Eq. (6) can be reduced to the Laguerre differential equation, so that its solution can be represented as

$$\mathcal{E}_k(E_y) = \exp\left(-\frac{1+i}{2}\sqrt{\frac{\omega}{D_0 E}}E_y\right) L_{\nu_k}\left((1+i)\sqrt{\frac{\omega}{D_0 E}}E_y\right) \quad (11)$$

where $L_\nu(\dots)$ is the Laguerre function§ and ν_k is related to the eigenvalue $\mathcal{C}_{y,k}$ via

$$\mathcal{C}_{y,k} = -\frac{(1+i)}{2}\sqrt{\frac{D_0 \omega}{E}}(2\nu_k + 1), \quad k = 1, 2, 3, \dots \quad (12)$$

The eigenvalues can be found by imposing the boundary conditions. The maximum energy of channeling oscillations in a bent channel with parabolic potential is given by $E_y^{\max} = U_{\max}(1-C)^2$, where $C = F_c/U'_{\max}$ is defined as a ratio of the centrifugal force F_c to the maximum value of the interplanar force $U'_{\max}$ [5]. Therefore, the density boundary condition has the form:

$$L_{\nu_k}\left((1+i)\sqrt{\frac{\omega}{D_0 E}}U_{\max}(1-C)^2\right) = 0. \quad (13)$$

Equation (13) has to be solved for ν_k . (the subscript k enumerates different roots of the equation) and the result has to be substituted into (12).

It is convenient to represent the eigenvalues in the form

$$\mathcal{C}_{y,k} = -\frac{\alpha_k(\kappa, C)}{L_d} - i\omega\theta_L^2\beta_k(\kappa, C). \quad (14)$$

Here $L_d = 4U_{\max}/(j_{0,1}^2 D_0)$ is the dechanneling length in a straight channel [10] ($j_{0,k}$ is k -th zero of the Bessel function $J_0(\varepsilon)$), $\theta_L = \sqrt{2U_{\max}/E}$ is the corresponding Lindhard's angle. We introduce the parameter

$$\kappa = \pi \frac{L_d}{\lambda} \theta_L^2, \quad (15)$$

where $\lambda = 2\pi/\omega$ is the spatial period of the modulation. The functions $\alpha_k(\kappa, C)$ and $\beta_k(\kappa, C)$ can be represented as

$$\alpha_k(\kappa, C) = \frac{\alpha_k(\kappa(1-C)^4)}{(1-C)^2} \quad (16)$$

$$\beta_k(\kappa, C) = (1-C)^2\beta_k(\kappa(1-C)^4) \quad (17)$$

Here $\alpha_k(\kappa) \equiv \alpha_k(\kappa, C=0)$ and $\beta_k(\kappa) \equiv \beta_k(\kappa, C=0)$ are the cooresponding functions for the straight channel which are found by solving numerically Eq. (13) combined with (12).

Using (8), one finds the solution of Eq. (7):

$$\mathcal{S}_{n,k}(s) = \exp\left\{-\frac{s}{L_d}\left[\alpha_k(\kappa, C) + (2n+1)\frac{\sqrt{\kappa}}{j_{0,1}}\right] - i\omega s\left[\frac{1}{2\gamma^2} + \theta_L^2\beta_k(\kappa, C) + \theta_L^2\frac{(2n+1)}{2j_{0,1}\sqrt{\kappa}}\right]\right\}. \quad (18)$$

§ At nonnegative integer values of ν , the Laguerre function is reduced to the well known Laguerre polynomials. In the general case that is relevant to our consideration, it can be represented by an infinite series: $L_\nu(\varepsilon) = \sum_{j=0}^{\infty} \prod_{m=0}^{j-1} (m - \nu) \varepsilon^j / (j!)^2$.

Hence, the solution of Eq. (4) is represented as

$$g(s; \xi, E_y) = \exp(-i\omega s) \sum_{n=0}^{\infty} \sum_{k=1}^{\infty} \mathbf{c}_{n,k} \Xi_n(\xi) \mathcal{E}_k(E_y) \mathcal{S}_{n,k}(s), \quad (19)$$

where the coefficients $\mathbf{c}_{n,k}$ are found from the particle distribution at the entrance of the crystal channel. Due to the exponential decrease of $\mathcal{S}_{n,k}(s)$ with s (see (18)), the asymptotic behaviour of $\tilde{g}(s; \xi, E_y)$ at large s is dominated by the term with $n = 0$ and $k = 1$ having the smallest value of the factor $[\alpha_k(\kappa, C) + (2n + 1)\sqrt{\kappa}/j_{0,1}]$ in the exponential. Therefore, at sufficiently large penetration depths, the particle distribution depends on s as $g(s; \xi, E_y) \propto \exp(-s/L_{\text{dm}} - i\omega/u_s s)$ where L_{dm} is the newly introduced parameter — *the demodulation length*:

$$L_{\text{dm}} = \frac{L_d}{\alpha_1(\kappa, C) + \sqrt{\kappa}/j_{0,1}} \quad (20)$$

and u_s is the phase velocity of the modulated beam along the crystal channel

$$u_s = \left[1 + \frac{1}{2\gamma^2} + \theta_L^2 \left(\beta_k(\kappa, C) + \frac{1}{2j_{0,1}\sqrt{\kappa}} \right) \right]^{-1}. \quad (21)$$

This parameter is important for establishing the resonance conditions between the undulator parameters and the radiation wavelength. It will be analysed elsewhere.

Figure 3. The ratio of the demodulation length L_{dm} (20) to the dechanneling length in the straight channel L_d versus the parameter κ (15) for different values of Tsyanov's factor C . The corresponding asymptotic values at $\kappa \rightarrow 0$ are shown by thin horizontal lines.

In this Letter we concentrate our attention on the demodulation length. This parameter represents the characteristic scale of the penetration depth at which a beam of channeling particles gets demodulated.

Fig. 3 presents the dependence of the ratio L_{dm}/L_d on the parameter κ . At $\kappa \rightarrow 0$, the demodulation length approaches $(1 - C)^2 L_d$ which is the dechanneling length in the

bent crystal. It is seen that the demodulation length is smaller than dechanneling length by only 20–30% at $\kappa \lesssim 1$ for C varying between 0 and 0.3. This is an important result, since it was proven for a number crystals channels [5] that the dechanneling length is sufficiently large to make the crystalline undulator feasible. According our present result, the demodulation process does not put essential additional restrictions on the undulator length and, therefore, the crystalline undulator can generate also coherent radiation provided that it is fed by a modulated beam. On the contrary, the ratio noticeably drops for $\kappa \gtrsim 10$. Therefore, further investigations are needed to clarify whether the lasing regime is feasible in this κ range.

The dependence of the parameter κ on the energy of the emitted photons, $\hbar\omega = 2\pi\hbar/\lambda$, is shown in Fig. 4. The calculation was done for 1 GeV|| positrons using the formula for the dechanneling length from [5, 10].

Figure 4. The parameter κ (15) versus the photon energy $\hbar\omega$ for different crystals and crystallographic planes.

As one sees from the figure, there exist such crystal channels that $\kappa = 1$ corresponds to $\hbar\omega = 100 - 300$ keV. Therefore, CUL is most suitable for the application in this photon energy range. The lower limit on the photon energy is dominated by a very strong absorption of the radiation in the crystal, while the upper limit on the photon energy is set by the decreasing value of L_{dm} .

According to our estimations, the brilliance as high as $10^{25} - 10^{26}$ Photons/(s mm² mrad² 0.1%BW) can be obtained in a CUL fed by a completely modulated positron beam with current 1 kA and particle density 10^{18} cm⁻³.

In conclusion, we have studied the propagation of a modulated particle beam in a bent planar crystal channel. It has been demonstrated that the beam preserves

|| Note that κ depends weakly (logarithmically) on the particle energy. Therefore, changing the beam energy by an order of magnitude would leave Fig. 4 practically unchanged.

its modulation at the penetration depths which are sufficient for producing coherent radiation with the photon energy of hundreds keV. This opens the prospects for creating intense monochromatic radiation sources in the frequency range which is unattainable for conventional free electron lasers. Developing suitable methods of beam modulation would be the next milestone on the way towards this goal.

This work has been supported in part by the European Commission (the PECU project, Contract No. 4916 (NEST)) and by Deutsche Forschungsgemeinschaft.
